Efficiently Heating Your Home

These days, more people are heating their homes with wood, even if they haven't taken the time to evaluate the benefits and costs.

The information contained in this guide helps you estimate heating costs and shows you how to get the most heat from your wood.

Why Wood?

Wood heat is often not the cheapest heat source and it requires more work. It is less convenient than heating with fuels fed automatically. Wood is dirty and requires more planning to use. Wood burning systems require more maintenance. However, if the cost of wood is low enough, you will save money over other methods. Then, too, you will also enjoy the warm fire and the feeling of self-sufficiency brought on by providing the source of your warmth, hands-on. For those who enjoy the work, cutting, splitting and stacking can be a pleasant form of exercise.

Cost comparisons between different woods and between wood and other fuels can easily be done using the steps in this guide. These steps assume you purchase your firewood and do not include installation costs or costs of improving the efficiency of an existing heating system.

Comparing Costs of Heat

To compare heating costs, you must convert costs of different fuels to cost per unit/heat. Cords of wood, gallons of oil, kilowatt hours of electricity, therms of natural gas and cubic feet of liquid propane gas must be converted to common heat content unit for comparison.

The kilowatt hour and the therm are precise quantities of energy. The volume of heat in a cord of wood can vary considerably and the potential heat in a cubic foot of wood is different for different species. The heating value of wood, the stoves used and frequently required stove adjustments make wood heating calculations less precise than other fuel sources.

Which Wood Is The Better Buy?

When different woods are available, a value comparison can be made using appropriate figures from Table 1. Follow these steps to find out which of your choices is the better buy:

- 1) Obtain from Table 1 the heat value per cord of wood for each of the woods you want to compare.
- 2) Divide the cost you pay for a cord of wood by the heat value per cord. The answer is the cost of a million BTUs of heat for that species.
- 3) Compare the costs for the species. The cheapest cost per million BTUs is the best buy.

Example: Both black oak at \$130/cord and incense cedar at \$120/cord are available. Assuming both cords are dry, which is the better buy? To get the cost per million BTUs, divide the cost per cord of each wood by its heat per cord from Table 1.

- **Black Oak:** \$130/cord divided by 22.6 million BTUs/cord equals \$5.75/million BTUs.
- **Incense Cedar:** \$120/cord divided by 16.0 million BTUs/cord equals \$7.50/million BTUs.

Compared in this way, it is easy to see that black oak is the less expensive heat source. In fact, if black oak were as much as \$170/cord, it would still be as cost efficient as incense cedar at \$120/cord.

**Table 1
Approximate Heat Content
Per Cord Of Different Woods**

Alder	15.7
Almond	32.9
Apple	27.5
Apricot	28.3
Avocado	20.7
CEDAR:	
Incense	16.0
Port Orford	17.6
Cherry	27.0
Chinkapin	18.9
Citrus	33.8
Cottonwood	14.0
Cypress, Monterey	19.3
Douglas-fir	21.5
Elm	20.7
EUCALYPTUS:	
Blue gum	28.0
Lemon scented gum	30.6
Mountain gum	24.3
Red gum	30.6
Rose gum	27.5
Fig	23.3
FIR:	
Grand	15.2
Red	16.1
White	15.7
LAUREL:	
Bay	23.3
California	23.3
Myrtle (Oregon)	23.3
Pepperwood	23.3
Madrone	24.8
Mahogany, mountain	39.8
Manzanita	32.0
Maple	19.6
OAK:	
Black	22.6
Blue	38.2
Canvon live	31.7
Coast live	28.5
Tanoak	26.1
White	28.2
Olive	37.3
Peach	32.5

Pear	32.0
PINE:	
Knobcone	20.5
Diagar	17.2
Lodgepole	17.3
Monterey	22.0
Ponderosa	18.3
Sugar	16.2
Plum	25.6
Redwood	18.5
WALNUT	
English	22.5
Black	23.5

*Wood specific gravity and heat value are both necessary for calculation of fuel value. Both have been determined for most woods but data were estimated for a few uncommon species, based on local laboratory experience.

Why Wood Heat Value Varies

The ratio between the chemical components of wood (lignin, cellulose and extractives) makes wood heat values vary by as much as 20 percent. Wood cell walls, made of lignin and cellulose, have a heating potential of about 8,500 BTU per pound, depending on the species. Extractives (resin and oils that give wood color, decay resistance and odor) have a heat content similar to that of lignin. Bark has a higher heat value than most wood.

In addition to the ratios of chemical and wood components, the dry weight per wood volume (wood density) is even more important. California fuel woods weigh from 22 to 50 pounds per cubic foot. California law requires that firewood be sold by the stacked cord, well stowed and packed. A cord is a volume of 128 cubic feet in a stack 4 feet wide by 8 feet long by 4 feet high (California Administrative Code Title 4, Ch 8 (2) 1, Sec. 2892) Volume and weight combine so that in a cord of cottonwood there is only half the energy contained in a cord of white oak, while a cord of alder has only 60 percent as much energy as a cord of tanoak.
